COMPLETE SUMMARY CONTENT

SCOPE

DISEASE/CONDITION(S)

Blunt abdominal trauma

GUIDELINE CATEGORY

Diagnosis

CLINICAL SPECIALTY

Emergency Medicine
Radiology
Surgery

INTENDED USERS

Health Plans
Hospitals
Managed Care Organizations

Physicians
Utilization Management

GUIDELINE OBJECTIVE(S)

To evaluate the appropriateness of initial radiologic examinations for patients with blunt abdominal trauma

TARGET POPULATION

Patients with blunt abdominal trauma. Penetrating trauma and pediatric cases are not considered.

INTERVENTIONS AND PRACTICES CONSIDERED

1. Plain x-ray
    - Upright chest x-ray
    - Supine and upright abdomen x-ray
    - Abdomen x-ray
2. Computed tomography
    - Abdomen and pelvis helical
    - Abdomen and pelvis non-helical
    - Cystogram – combined with computed tomography of the abdomen and pelvis
3. Invasive
    - Angiography embolization
    - Renal angiogram
4. Ultrasound
    - Screen for hemoperitoneum
    - Organ sonogram
    - Bladder sonogram
5. Magnetic resonance imaging
    - Organ evaluation
    - Diaphragm evaluation
    - Kidneys, bladder evaluation
6. Other
    - Retrograde urethrogram
    - IVU
    - Plain film cystogram

MAJOR OUTCOMES CONSIDERED

Utility of radiologic examinations in differential diagnosis

METHODOLOGY

METHODS USED TO COLLECT/SELECT EVIDENCE

Searches of Electronic Databases

DESCRIPTION OF METHODS USED TO COLLECT/SELECT THE EVIDENCE

The guideline developer performed literature searches of recent peer-reviewed medical journals, primarily using the National Library of Medicine´s MEDLINE database. The developer identified and collected the major applicable articles.

NUMBER OF SOURCE DOCUMENTS

The total number of source documents identified as the result of the literature search is not known.

METHODS USED TO ASSESS THE QUALITY AND STRENGTH OF THE EVIDENCE

Expert Consensus (Delphi Method)
Weighting According to a Rating Scheme (Scheme Not Given)

RATING SCHEME FOR THE STRENGTH OF THE EVIDENCE

Not applicable

METHODS USED TO ANALYZE THE EVIDENCE

Systematic Review with Evidence Tables

DESCRIPTION OF THE METHODS USED TO ANALYZE THE EVIDENCE

One or two topic leaders within a panel assume the responsibility of developing an evidence table for each clinical condition, based on analysis of the current literature. These tables serve as a basis for developing a narrative specific to each clinical condition.

METHODS USED TO FORMULATE THE RECOMMENDATIONS

Expert Consensus (Delphi)

DESCRIPTION OF METHODS USED TO FORMULATE THE RECOMMENDATIONS

Since data available from existing scientific studies are usually insufficient for meta-analysis, broad-based consensus techniques are needed to reach agreement in the formulation of the Appropriateness Criteria. Serial surveys are conducted by distributing questionnaires to consolidate expert opinions within each panel. These questionnaires are distributed to the participants along with the evidence table and narrative as developed by the topic leader(s). Questionnaires are completed by the participants in their own professional setting without influence of the other members. Voting is conducted using a scoring system from 1-9, indicating the least to the most appropriate imaging examination or therapeutic procedure. The survey results are collected, tabulated in anonymous fashion, and redistributed after each round. A maximum of three rounds is conducted and opinions are unified to the highest degree possible. Eighty (80) percent agreement is considered a consensus. If consensus cannot be reached by this method, the panel is convened and group consensus techniques are utilized. The strengths and

weaknesses of each test or procedure are discussed and consensus reached whenever possible.

RATING SCHEME FOR THE STRENGTH OF THE RECOMMENDATIONS

Not applicable

COST ANALYSIS

A formal cost analysis was not performed and published cost analyses were not reviewed.

METHOD OF GUIDELINE VALIDATION

Internal Peer Review

DESCRIPTION OF METHOD OF GUIDELINE VALIDATION

Criteria developed by the Expert Panels are reviewed by the American College of Radiology (ACR) Committee on Appropriateness Criteria and the Chair of the ACR Board of Chancellors.

RECOMMENDATIONS

MAJOR RECOMMENDATIONS

ACR Appropriateness Criteria™

Clinical Condition: Blunt Abdominal Trauma, Adults

Variant 1: Stable patient.

Radiologic Exam Procedure	Appropriateness Rating	Comments
Plain X-ray		
Upright chest x-ray	8	
Supine and upright abdomen x-ray	8	
Computed Tomography		
Abdomen and pelvis helical	8	
Abdomen and pelvis non-helical	8	
Invasive		

Angiography embolization	8	Not a screening procedure. Angiography is indicated to delineate and treat active bleeding or other lesions amenable to angiographic therapy, but only when this type of lesion is first detected or suspected, either by computed tomography or by some other means.
Ultrasound		
Screen for hemoperitoneum	4	Low sensitivity of ultrasound to injuries that require surgery (active hemorrhage, viscus perforation) and its inability to exclude injuries that require in-hospital observation lessen the usefulness of ultrasound for key triage decisions.
Organ sonogram	3	
Magnetic Resonance Imaging		
Organ evaluation	2	
Diaphragm evaluation	2	
Appropriateness Criteria Scale 1 2 3 4 5 6 7 8 9 1=Least appropriate 9=Most appropriate		

Variant 2: Unstable patient.

Radiologic Exam Procedure	Appropriateness Rating	Comments
Plain X-ray		
Chest x-ray	7	
Abdomen x-ray	6	
Ultrasound		
Screen for hemoperitoneum	7	
Organ sonogram	4	
Invasive		

Angiography embolization	4	
Computed Tomography		
Abdomen and pelvis helical	4	
Abdomen and pelvis non-helical	3	Clinical judgment needed on stability of patient versus need for diagnostic information.
Magnetic Resonance Imaging		
Organ evaluation	2	
Diaphragm evaluation	2	
Appropriateness Criteria Scale 1 2 3 4 5 6 7 8 9 1=Least appropriate 9=Most appropriate		

Variant 3: Hematuria > 35 RBC/HPF (stable).

Radiologic Exam Procedure	Appropriateness Rating	Comments
Plain X-ray		
Upright chest x-ray	8	
Supine and upright abdomen x-ray	8	
Computed Tomography		
Abdomen and pelvis	8	
Cystogram-combined with computed tomography abdomen and pelvis	7	
Other		
Retrograde urethrogram	7	If urethral injury is suspected.
Intravenous urography (IVU)	4	
Plain film cystogram	4	
Invasive		

Renal angiogram	4	
Ultrasound		
Organ sonogram	3	
Bladder sonogram	3	
Magnetic Resonance Imaging		
Kidneys, bladder evaluation	2	
Appropriateness Criteria Scale 1 2 3 4 5 6 7 8 9 1=Least appropriate 9=Most appropriate		

Excerpted by the National Guideline Clearinghouse (NGC).

Summary

This review considers only the issue of blunt abdominal trauma in adults. Penetrating trauma and pediatric cases are not considered.

Category A

Hemodynamically unstable patients presenting to the emergency room with clinically obvious major abdominal trauma and with unresponsive profound hypotension need rapid clinical evaluation and immediate resuscitation with volume replacement. If such unstable patients do not respond to resuscitation (become hemodynamically stable), and if they have clear clinical evidence of abdominal injury, they should go immediately to the operating room without imaging . However, ultrasound performed by an experienced sonologist to check for intraperitoneal free fluid may quickly provide information that can support a decision to operate, with the caveat that the false negative rate is at least 15%. More detailed ultrasound to check for organ injury takes too long in this setting and suffers from poor sensitivity. There is now some agreement that diagnostic peritoneal lavage is obsolete because of its invasive nature, lack of specificity, and inability to predict the need for therapeutic surgery.

Category B

Hemodynamically stable patients or patients with mild to moderate responsive hypotension presenting to the emergency room after blunt abdominal trauma, and patients who stabilize after initial resuscitation are in a separate category. These patients typically have a history of significant trauma and have at least moderate suspicion of intra-abdominal injury based on clinical signs and symptoms. For these patients, two decisions need to be made: (1) Is urgent therapeutic surgery or angiography needed? (2) If surgery is not needed, is a period of close observation warranted? The decision to proceed with urgent surgery depends on

the identification of specific criteria that predict that the surgery will be successfully therapeutic: active hemorrhage, parenchymal "blush" or pseudoaneurysm in the spleen, or perforation of a hollow viscus (including the pancreatic duct). In patients with active hemorrhage or pseudoaneurysm of the spleen, angiographic embolization may also be therapeutic. The decision to operate urgently does not solely depend on the identification of hemoperitoneum or the identification of parenchymal injury to the liver or spleen, because most patients in this category ultimately do not need surgery. However, accurate identification of hemoperitoneum or organ injury is important because patients with these findings require at least a period of close observation. Patients with multiple organ injury or significant active bleeding may need surgery even if they are hemodynamically stable. Conversely, stable patients with isolated organ injury may not need surgery (or may need only angiography plus embolization) even with a large amount of hemoperitoneum.

Either way, time is available in such patients to obtain chest and abdominal radiographs, a hematocrit plus blood chemistries, and a urinalysis. If a reliable abdominal exam can be performed (the patient is conscious and does not need prolonged anesthesia for other procedures) and all the above preliminary tests are unremarkable, a period of close observation may be all that is needed. However, if a reliable abdominal exam cannot be performed (patient is unconscious or prolonged nonabdominal surgery is anticipated) or if a clinical evaluation suggests organ injury, hemoperitoneum, or peritonitis, further imaging is needed.

At this point, ultrasound is not a good modality for further imaging because it misses up to 25% of liver and spleen injuries, most renal injuries, and virtually all pancreatic, mesenteric, and gut injuries. It also misses a high proportion of retroperitoneal hemorrhage and of bladder rupture. Combining the results for ultrasound in 1535 abdominal trauma patients from the eight most recently published series yields an average sensitivity for hemoperitoneum of 88% and for organ injury of 74%. Unfortunately, a negative ultrasound (absence of hemoperitoneum) does not rule out significant organ or viscus injury that might require surgery or observation.

Although ultrasound is 63% sensitive to moderate amounts of free intraperitoneal fluid (compared with computed tomography), 400-600 cc's are needed for ultrasound detection of fluid in the trauma setting. Almost regardless of volume, an ultrasound diagnosis of free fluid alone does not predict that surgery is needed or that surgery will be therapeutic. In addition, in the best of hands, there is at least a 15% false negative rate for detecting hemoperitoneum with ultrasound. Further, ultrasound is quite insensitive in detecting organ injury: 62% in the spleen and 14% in the liver compared with computed tomography and operative findings. Ultrasound poorly identifies active hemorrhage and also does not accurately predict the need for surgery in splenic injuries. Ultrasound is insensitive to perforation of gut and to pancreatic injury. For these reasons, ultrasound is not very useful in deciding when a patient needs urgent therapeutic surgery or angiography. For the same reasons, ultrasound is not an accurate modality to determine if a patient needs a period of close observation. Although there is a body of literature that suggests ultrasound can be used to triage trauma patients in this category, this literature has been criticized for using clinical outcome as a gold standard and because the surgeon authors themselves judged whether a laparotomy was therapeutic without objective blinded review of this judgment. Of

note, the more rigorous analyses in this body of literature may be coming from radiology departments.

In contrast, for category B trauma patients, computed tomography accurately predicts if therapeutic surgery is urgently needed by identifying active hemorrhage, splenic injury (either parenchymal contrast blush or pseudoaneurysm, gut perforation, and pancreatic injury. For these reasons, computed tomography is an excellent modality for deciding if a patient needs urgent therapeutic surgery or is a candidate for therapeutic angiography. Because computed tomography is sensitive in detecting both hemoperitoneum and injury to the liver (sensitivity 93%) and spleen (sensitivity 95%), it is an accurate modality for deciding if a patient needs a period of close observation. The trend toward placing helical computed tomography scanners close to or in emergency departments has substantially diminished both the delay in getting patients to the computed tomography scanner and has decreased actual scan time to less then 60 seconds. In some circumstances, results from a helical computed tomography of the abdomen and pelvis can be obtained faster than results from a detailed ultrasound that includes evaluation of abdominal organs and gut.

If helical computed tomography with rapid image process capability is available in or next to an emergency department, abdominal computed tomography can be performed in about 4 minutes - exclusive of time needed for patient transport, computed tomography scan setup, and photography of images. Including all time requirements, patient turnaround with rapid-process helical computed tomography can be less 15 minutes for a trauma patient. For nonhelical incremental computed tomography, turnaround time is somewhat longer, usually 25 to 40 minutes. Scanning multiple body regions increases these times variably.

An experienced radiologist should carefully examine images on film and at the computed tomography console, where images can be altered to seek bone injury, pneumoperitoneum, or subtle organ injury. Particular care should be taken to find minimal injury of the spleen because these patients may need observation for potential delayed hemorrhage. In some instances, stable patients with more severe injuries of the liver or spleen plus hemoperitoneum may be managed conservatively with only close observation. It should be noted, however, that various schemes for using computed tomography to grade liver or spleen lacerations are not helpful in deciding whether a patient needs surgery. This decision must be based on the clinical status of the patient in combination with the image findings. If evidence of active hemorrhage is discovered clinically, or on computed tomography exams, the patient may be taken to the operating room or undergo arteriography plus embolization to control the hemorrhage.

The computed tomography exam should be carefully examined for subtle signs of pancreatic injury because these patients may need immediate surgery or close observation for signs of complications. Duodenal perforation produces subtle but frequent findings on computed tomography, e.g., typically extraluminal air or contrast in the retroperitoneum or elsewhere; these findings mandate surgical intervention. Duodenal hematoma may not require surgery but does need close observation. Other gut injury or perforation produces direct or indirect findings on computed tomography in 50% to 88% of cases. However, if the computed tomography is negative for gut injury in the face of a high clinical suspicion,

diagnostic peritoneal lavage or laparoscopy may be used to search for extravasated succus or other evidence.

There may be a rationale for creating a subcategory of stable patients with trivial trauma, a low clinical index of suspicion, and no signs or symptoms of intraabdominal injury. In such patients, a negative ultrasound alone may be adequate to release the patient from observation at a lower cost than if computed tomography had been used. Computed tomography, however, is necessary if there are any positive findings on ultrasound.

It may also be reasonable to use computed tomography, in conjunction with the clinical information, to decide whether to observe patients in the hospital for a day, or send them home promptly at the completion of their investigation in the emergency department. The high sensitivity of computed tomography in detecting injuries that require observation in the hospital means that a negative computed tomography may be adequate to release the patient to home. Ultrasound has a substantially lower sensitivity for injuries that must be observed in the hospital. For this reason, a negative ultrasound is not adequate to safely release the patient to home. This weakness of ultrasound is reflected in the design of many outcomes-based investigations on the use of ultrasound in trauma: all keep patients with a negative ultrasound in the hospital for a period of observation of one to two days before release.

Category C

Patients with hematuria require some modification to the imaging workup. Patients with microscopic hematuria (less than 35 red blood cells per HPF) do not need specific urinary tract imaging. All patients with microscopic hematuria greater than 35 red blood cells per HPF, with macroscopic hematuria, or with fracture/diastasis of the symphysis pubis and its rami plus any hematuria need imaging of the urinary tract. For imaging, if the urethral meatus has gross blood, if there is a floating prostate, or if a Foley catheter cannot be passed, a retrograde urethrogram should first be performed to rule out urethral injury. However, if clinical evaluation or the urethrogram indicates no urethral injury, a computed tomography cystogram should be added to the abdominal computed tomography (see appendix of the original guideline document). Computed tomography images should be examined carefully for evidence of renal perfusion, hemorrhage, or extravasation of contrast or urine from the kidney or bladder. Two studies have documented the poor ability of ultrasound to detect injuries of the kidney. All but the worst renal injuries are treated with observation; bladder rupture is usually treated with surgical repair.

CLINICAL ALGORITHM(S)

Algorithms were not developed from criteria guidelines.

EVIDENCE SUPPORTING THE RECOMMENDATIONS

TYPE OF EVIDENCE SUPPORTING THE RECOMMENDATIONS

The recommendations are based on analysis of the current literature and expert panel consensus.

BENEFITS/HARMS OF IMPLEMENTING THE GUIDELINE RECOMMENDATIONS

POTENTIAL BENEFITS

Selection of appropriate radiologic imaging procedures for evaluation of patients with blunt abdominal trauma.

POTENTIAL HARMS

None identified

QUALIFYING STATEMENTS

QUALIFYING STATEMENTS

An American College of Radiology (ACR) Committee on Appropriateness Criteria and its expert panels have developed criteria for determining appropriate imaging examinations for diagnosis and treatment of specified medical condition(s). These criteria are intended to guide radiologist, radiation oncologist, and referring physicians in making decisions regarding radiologic imaging and treatment. Generally, the complexity and severity of a patient's clinical condition should dictate the selection of appropriate imaging procedures or treatments. Only those exams generally used for evaluation of the patient's condition are ranked. Other imaging studies necessary to evaluate other co-existent diseases or other medical consequences of this condition are not considered in this document. The availability of equipment or personnel may influence the selection of appropriate imaging procedures or treatments. Imaging techniques classified as investigational by the U.S. Food and Drug Administration (FDA) have not been considered in developing these criteria; however, study of new equipment and applications should be encouraged. The ultimate decision regarding the appropriateness of any specific radiologic examination or treatment must be made by the referring physician and radiologist in light of all the circumstances presented in an individual examination.
